Abstract

Fractal image coding technique has attracted a degree of interest for its low bit rate. But the reconstructed image is of medium quality. This problem has prevented fractal technique from being practically used. In order to improve the compression fidelity, a new affine transformation is proposed in the paper. Meanwhile, its contractivity requirement is analyzed and the optimal parameters is derived using the least square method. The new affine transformation has been practically used in image coding. Experiments show that the PSNR can reach 28.7dB at the compression ratio(CR) of 16.4 for $256 \times 256 \times 8$ "Lena" image. Comparison with other fractal coding schemes shows that the new affine transformation can improve the reconstructed image quality efficiently.

1. Introduction

It is in the recent few years that fractal theory was applied in the field of image coding. In 1988, M. F. Barnsley and A.D.Sloan proposed using fractals generated by iterated function system(IFS) to encode or compress images[1]. But the first automatic robust block-based fractal image coding scheme which can compress any digital monochrome image was proposed by A.E.Jacquin in 1990[2]. After that, some other papers which are related to fractal image coding were published[3-9]. But most of them are based on Jacquin's scheme.

However, experiments show that the fractal reconstructed image is of medium quality. The best result reported in [2] is that the PSNR=27.7 dB and the bit rate=0.68 bpp for $256 \times 256 \times 6$ "Lena" image. In [2], some measures such as two-level partitioning technique have been used to improve the fidelity. If only one-level partitioning is used, the PSNR will be even lower. The problem has attracted a degree of attention.
In this paper, a new affine transformation is proposed to improve the image quality. Its contractivity requirement is also analyzed and the optimal parameters is derived. At last, some experimental results and comparison with other fractal coding schemes are presented.

2. The mathematical principle of fractal coding

Let \((\Omega, \lambda)\) denote a complete metric space. The elements of the space are digital images. \(\lambda\) is a given metric. The original image \(X_{\text{orig}}\) is one element of the space. The fractal coding procedure of \(X_{\text{orig}}\) is to construct a transformation \(T: \Omega \rightarrow \Omega\), which satisfies the following conditions:

(i) For any \(p_1, p_2 \in \Omega\), \(\lambda(T(p_1), T(p_2)) \leq s \cdot \lambda(p_1, p_2)\), where \(0 \leq s < 1\);

(ii) \(T(X_{\text{orig}}) = X_{\text{orig}}\).

From condition (i), we know that \(T\) is a contractive transformation. The Contractive Mapping Fixed Point Theorem ensures that \(T\) has a unique fixed point and the fixed point can be found by iteration of \(T\). Condition (ii) tells us that \(X_{\text{orig}}\) is an approximate fixed point of \(T\). So \(X_{\text{orig}}\) can be reconstructed by applying \(T\) on any initial image \(X_0\) iteratively. If \(T\) can be stored compactly, then it is called the compressed data of \(X_{\text{orig}}\). Therefore, \(X_{\text{orig}}\) is compressed.

In practical use, it is difficult to construct such \(T\) directly. It is usually constructed by the union of a series of contractive affine transformations.

\[
T = \bigcup_{i \in N} T_i
\]

where \(T_i\) is the \(i\)th contractive affine transformation, \(N\) is the total number of the affine transformations, and

\[
T(X_{\text{orig}}) = \bigcup_{i \in N} T_i(D_i)
\]

where \(D_i \subseteq X_{\text{orig}}\).

The performance of fractal image coding mainly depends on the affine transformations. In the next section, we will propose a new affine transformation.

3. The new affine transformation

The new affine transformation we proposed is:

\[
\begin{bmatrix}
X \\
Y \\
Z
\end{bmatrix} =
\begin{bmatrix}
a & b & 0 \\
c & d & 0 \\
0 & 0 & g(z)
\end{bmatrix}
\begin{bmatrix}
x \\
y \\
1
\end{bmatrix} +
\begin{bmatrix}
e \\
f \\
0
\end{bmatrix}
\]

(3)
(x,y) denotes the coordinates of a pixel to be transformed. z denotes the pixel intensity of (x,y). (X,Y) denotes the coordinates of the pixel transformed. Z denotes the intensity of (X,Y). a, b, c, d, e, f are parameters of the affine transformation.

The affine transformation used in Jacquin's scheme is only a special case of (3) that \( g(z) = tz + o \). Obviously, it is a linear one containing only a scaling and an offset. Its approximation ability is quite limited. The new affine transformation generalizes the pixel intensity approximation. So it can provide better approximation.

For convenience of the following discussion, we rewritten (3) as (4).

\[
\begin{bmatrix}
X \\
Y \\
Z
\end{bmatrix} = \begin{bmatrix}
B & 0 \\
0 & g(z)
\end{bmatrix} \begin{bmatrix}
x \\
y
\end{bmatrix} + \begin{bmatrix}
e \\
f
\end{bmatrix}
\]

where \( B = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \)

\[ (4) \]

3.1 The contractivity condition of the new affine transformation

In order to make the decoding procedure converge, the affine transformation must be contractive. So we must discuss the contractivity condition of the new affine transformation. First we introduce the definition of contractivity.

**Definition 3.1.1.** A transformation w is said to be contractive if for any two points \( \bar{x}_1 \) and \( \bar{x}_2 \), the distance \( \lambda(w(\bar{x}_1), w(\bar{x}_2)) \leq s \cdot \lambda(\bar{x}_1, \bar{x}_2) \) where \( 0 \leq s < 1 \).

In this paper, for any vector \( \bar{x} = (x_1, x_2, \ldots, x_n)^T \), the vector norm used is:

\[ \|\bar{x}\|_2 = \left( \sum x_i^2 \right)^{1/2} \]

and the distance measure is:

\[ \lambda(\bar{x}_1, \bar{x}_2) = \|\bar{x}_1 - \bar{x}_2\|_2 \]

for any two vectors \( \bar{x}_1, \bar{x}_2 \).

Next, we put forward a theorem about the contractivity of the new affine transformation.

**Theorem 3.1.1.** Suppose we already know B is a contractive transformation(in practical coding procedure, B maps a large block onto a small one, so the condition is usually satisfied), if \( |g'(t)| \leq s \), \( 0 \leq s < 1 \), then transformation (4) is a contractive transformation. where \( g'(z) \) is the derivative of \( g(z) \). \( |g'(z)| \) is the absolute value of \( g'(z) \).

**Proof.** For any two vectors \( \bar{x}_1 = (x_1, y_1, z_1)^T \), \( \bar{x}_2 = (x_2, y_2, z_2)^T \), the transformed vectors are \( \bar{X}_1 = (X_1, Y_1, Z_1)^T \), \( \bar{X}_2 = (X_2, Y_2, Z_2)^T \), then
\[
\begin{align*}
\tilde{X}_1 - \tilde{X}_2 &= \begin{bmatrix} X_1 - X_2 \\ Y_1 - Y_2 \\ Z_1 - Z_2 \end{bmatrix} = \begin{bmatrix} a & b & 0 \\ c & d & 0 \\ 0 & 0 & g(z_1) - g(z_2) \end{bmatrix} \begin{bmatrix} x_1 - x_2 \\ y_1 - y_2 \\ 1 \end{bmatrix} \\
&= \begin{bmatrix} B & 0 \\ 0 & g(z_1) - g(z_2) \end{bmatrix} \begin{bmatrix} x_1 - x_2 \\ y_1 - y_2 \\ 1 \end{bmatrix}
\end{align*}
\]

For \( B \) is a contractive transformation, according to the definition of contractivity, there exists a \( s_i, 0 \leq s_i < 1 \), which satisfies
\[
\sqrt{(X_1 - X_2)^2 + (Y_1 - Y_2)^2} \leq s_i \cdot \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}
\]

In terms of Lagrange Mean-value Theorem
\[
Z_1 - Z_2 = g(z_1) - g(z_2) = g'(\xi) \cdot (z_1 - z_2), \text{where } \xi \in (z_1, z_2)
\]
So \( \sqrt{(Z_1 - Z_2)^2} = |g'(\xi)| \cdot \sqrt{(z_1 - z_2)^2} \leq s \cdot \sqrt{(z_1 - z_2)^2} \)

Let \( s_i = \max\{s_i, s\} \),
so \( \sqrt{(X_1 - X_2)^2 + (Y_1 - Y_2)^2 + (Z_1 - Z_2)^2} \leq s_i \cdot \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2 + (z_1 - z_2)^2} \)

So the transformation is contractive.

\[
\text{4. Application of the new affine transformation to image coding}
\]

\[\text{4.1 The coding scheme}\]

Let \( X_{\text{org}} \) be the original image. We assume that the size of \( X_{\text{org}} \) is \( 256 \times 256 \times 8 \). Before compressing, we subtract 128 from all pixels of the image. This ensures that the sum total of the pixels is approximately zero. \( X_{\text{org}} \) is first partitioned into \( 8 \times 8 \) range blocks and \( 16 \times 16 \) domain blocks which are denoted as \( R_1, R_2, \ldots, R_M \) and \( D_1, D_2, \ldots, D_D \) respectively. This is similar to [2], but only one-level partitioning is used in our experiments.

For any range block \( R_i \), we search for a suitable affine transformation \( T_i \) and a domain block \( D_j \) to satisfy the following equation as well as possible.

\[
R_i = T_i(D_j)
\]

That is to say, we must find suitable \( T_i \) and \( D_j \) to make \( T_i(D_j) \) and \( R_i \) to be similar to each other.

The affine transformation \( T_i \) maps a \( 16 \times 16 \) domain block onto a \( 8 \times 8 \) block, rotates or reflects the block and processes the pixel intensity. All the above functions are determined by the coefficients of the affine transformation \( T_i \), but the coefficients are difficult to determine, quantize and store. Usually we replace \( T_i \) with an equivalent compound transformation.
\[ T_j = G \circ \tau \circ \phi \]  \hspace{1cm} (6)

So (5) changes to
\[ R_j = G \circ \tau \circ \phi(D_j) \]  \hspace{1cm} (7)

Where \( \phi \) is x-y plane contractivity transformation which maps \( D_j \) onto a \( 8 \times 8 \) block, \( \tau \) is one of the eight rotation and flip operation proposed in[2]. \( G \) is the pixel intensity processor. Let \( z_i \) be the \( i \)th pixel intensity of \( \tau \circ \phi(D_j) \), then the \( i \)th pixel intensity of \( G \circ \tau \circ \phi(D_j) \) is \( g(z_i) \). Let \( Z_i \) denote the \( i \)th pixel intensity of \( R_i \), then the coding procedure of \( R_i \) is to select suitable \( G, \tau, D_j \) to minimize the following distortion
\[ \text{Error} = \sum_{i=1}^{K} (Z_i - g(z_i))^2 \]  \hspace{1cm} (8)

where \( K \) is the total number of the pixels in the range block.

When \( G, \tau \) and \( D_j \) are found, we store the parameters. Then the range block is encoded. When every range block is encoded in turn, the original image \( X_{\text{orig}} \) is encoded. Next we will discuss some problems about the determination and storation of the parameters.

4.2. The optimal parameters

In transformation (3), \( g(z) \) can be any form. In our experiments, \( g(z) = \alpha_1 z + \alpha_2 z^2 + o \). So the distortion (8) changes to
\[ \text{Error} = \sum_{i=1}^{K} (Z_i - \alpha_1 z_i - \alpha_2 z_i^2 - o)^2 \]  \hspace{1cm} (9)

The parameters \( \alpha_1, \alpha_2, o \) should minimize the distortion. Next we use the least square method to determine the parameters.

According to the least square method, we get the following equation group.
\[
\begin{align*}
\frac{\partial \text{Error}}{\partial \alpha_1} &= -2 \sum_{i=1}^{K} (Z_i - \alpha_1 z_i - \alpha_2 z_i^2 - o) z_i = 0 \\
\frac{\partial \text{Error}}{\partial \alpha_2} &= -2 \sum_{i=1}^{K} (Z_i - \alpha_1 z_i - \alpha_2 z_i^2 - o) z_i^2 = 0 \\
\frac{\partial \text{Error}}{\partial o} &= -2 \sum_{i=1}^{K} (Z_i - \alpha_1 z_i - \alpha_2 z_i^2 - o) = 0
\end{align*}
\]  \hspace{1cm} (10)

Solve Equ. (10), we can get the optimal parameters.
\[
\alpha_i - (Z_i - Ze)(z_i^2 - z^2) - (Z_i - Ze)(z_i^2 - z^2) (z_i - z)
\]
\[
\alpha_z - \frac{(Z_i - Ze)(z_i^2 - z^2)^2 - (Z_i - Ze)(z_i^2 - z^2) (z_i - z)}{z_i^2 - z^2}
\]
\[
o = Z - \alpha_i z - \alpha_z z^2
\]

where
\[
\bar{Z} = \frac{1}{K} \sum_{i=1}^{K} Z_i,
\]
\[
\bar{z} = \frac{1}{K} \sum_{i=1}^{K} z_i,
\]
\[
\bar{z}^2 = \frac{1}{K} \sum_{i=1}^{K} z_i^2,
\]
\[
\bar{z}^3 = \frac{1}{K} \sum_{i=1}^{K} z_i^3.
\]

After \( \alpha_i, \alpha_z, o \) are calculated, we must verify if the parameters satisfy the
contractivity condition mentioned in Theorem 3.1.1. Sometimes, the parameters do
not satisfy the contractivity condition.

According to Theorem 3.1.1, \( \alpha_i, \alpha_z, o \) should satisfy the following equation
\[
|g'(z_i)| = |\alpha_i + 2\alpha_z z_i| < 1
\]
(12)

Therefore,
\[
-1 < \alpha_i + 2\alpha_z z_i < 1
\]
(13)

where \( z_i \) is the pixel intensity of the block \( \tau o \phi(D_j) \). Every pixel of the block
\( \tau o \phi(D_j) \) must satisfy Equ. (13). If we examine every pixel, the computing is too
complex. Analyzing Equ. (13), we find that Equ. (13) is equivalent to the following
two equations.
\[
-1 < \alpha_i + 2\alpha_z z_{\text{max}} < 1
\]
(14)
\[
-1 < \alpha_i + 2\alpha_z z_{\text{min}} < 1
\]
(15)

where \( z_{\text{max}} \) and \( z_{\text{min}} \) are the maximum pixel and the minimum pixel of the block
\( \tau o \phi(D_j) \) respectively.

If \( \alpha_i, \alpha_z, o \) do not satisfy Equ. (14) and Equ. (15), the group of parameters can
not be used, we will compute the next optimal parameters and examine their
contractivity.

When the parameters are calculated and examined, we will quantize and store
them.

4.3 The quantization of the parameters

When \( D_j, G, \tau \) which satisfy equation (7) are found, we must quantize and store
the parameters. The parameters needed to be stored are: The position information of
\( D_j \), the rotation and flip operation \( \tau, \alpha_i, \alpha_z, o \)

The bit allocations are:
(i) The position information of \( D_j \)
The size of the original image is $256 \times 256$ and the neighboring domain blocks separate 4 pixels, so it needs $6 + 6 = 12$ bits to store the coordinates of the domain blocks $D_j$.

(ii) The rotation and flip operation $\tau$

There are eight kinds of rotation and flip operations, so it needs 3 bits to store it. $\alpha_1, \alpha_2, \theta$ are difficult to quantize. Next, we discuss their quantization.

The distribution curves of $\alpha_1, \alpha_2, \theta$ obtained from the compression of "Lena" image are shown in Fig. 1 (a), (b) and (c).

![Graphs showing distribution of parameters](image)

Fig. 3 (a) The distribution curve of $\alpha_1$.

(b) The distribution curve of $\alpha_2$.

(c) The distribution curve of $\theta$.

(iii) From Fig.1(a), we find that most of $\alpha_1$ varies between -1.5 to 1.5. So we quantize it in the following way.
If \(-1.55 < \alpha_1 < 1.55\), then \(0 \leq QUAN\left[\frac{\alpha_1}{0.1}\right]+15 \leq 30\). where \(QUAN[\cdot]\) is a function which takes the integer nearest to its variable. Obviously it needs 5 bits to store it.

If \(\alpha_1 \geq 1.55\) or \(\alpha_1 \leq -1.55\), then let \(p[\alpha_1] = SIGN[\alpha_1] \cdot ABS[\alpha_1] - 1.5\), where 
\[
SIGN[\alpha_1] = \begin{cases} 
1, & \text{if } \alpha_1 > 0 \\
-1, & \text{if } \alpha_1 < 0
\end{cases}
\]

\(ABS[\alpha_1]\) takes the absolute value of \(\alpha_1\). Then, as for \(p[\alpha_1]\), its distribution property is similar to \(\alpha_1\). So we can use the above way to quantize it, but this time the flag code \((1111)_{2}\) should be placed forward.

(iii) From Fig. 1(b), we find that most \(\alpha_2\) satisfy
\[
-15.5 < \frac{\alpha_2}{10^3} < 15.5
\]  \hspace{1cm} (16)

So, we can use the similar way to quantize and store \(\alpha_2\).

(v) From Fig. 1(c), we find that most \(\nu\) distribute between -128 to 127. So if \(-128.5 < \nu < 126.5\) then
\[
0 \leq QUAN[\nu]+128 < 254
\]  \hspace{1cm} (17)

It needs 8 bits to store it. If \(\nu \leq -128.5\) or \(\nu \geq 126.5\), we can use a way similar to (iii), but the flag code \((11111111)_{2}\) should be placed forward.

5. Experimental Results

Experiment 1.

The first experiment is used to test if the new affine transformation can improve the image quality. The original image used is the 256×256×8 standard image "Lena" which is shown in Fig. 2. We have compressed the original image using both the traditional method[2] and the method proposed in the paper. In this experiment, only one-level partitioning technique is used in both schemes. The size of the range block is 8×8, and the domain block size is 16×16, we divide the range blocks into four kinds to process them differently as in[2]. Compression ratio (CR) and peak-to-peak signal-to-noise ratio (PSNR) are chosen as criterion of comparison. The result is:

When using the traditional method, the compression ratio CR=17.8, the PSNR=24.9 dB.

When using the method proposed in the paper, the compression ratio CR=16.4, the PSNR=28.7 dB.

The decoded image are shown in Fig. 3 and Fig. 4.

Comparing Fig. 3 with Fig. 4, we can easily find that the fidelity of Fig. 4 is better than that of Fig. 3, especially in the edge of the column in the image. Comparing the PSNR and CR indicates that PSNR can increase nearly 4 dB while CR decreases a little. So the new affine transformation can improve the image quality.
One important point must be mentioned in the decoding procedure. For the case where the affine transformation is linear, the contractivity condition does not depend on the gray level of the domain pixels, therefore any initial image can be used as the starting point of the decoding process. The new affine transformation discussed in this paper has the second order term, therefore the contractivity of each transformation does depend on the gray level of the pixels in the domain blocks, as shown in Equ. (14) and Equ. (15). Therefore the convergence of the decoding scheme depends on the initial image used as the starting point of the decoding process. In this experiment, when a black image whose gray is near zero is chosen as the initial image, the decoding can converge, but when the gray is near 127 or -128 (because in the encoding procedure, the original image has been subtracted 128 from all pixels), the decoding does not. The un converged reconstruction sequence is shown in Fig. 5. We find that there are a lot of white and black points in the iteration image and as the transformations iterate, the number of white and black points increases quickly, the decoding image becomes disorderly. This problem affects the practical usage of the new affine transform.

But we found that when a limitation is applied after each iteration, the decoding can be made to converge. The limitation used was:

After each iteration, the gray of the iteration image is limited within -128 and 127. That is:

If $z_i > 127$, let $z_i = 127$;
If $z_i < -128$, let $z_i = -128$;
If $-128 \leq z_i \leq 127$, $z_i$ remains unchanged.

Where $z_i$ is the gray level of the iteration image.

Though this limitation was sufficient for the converge for the image tested, a more rigorous limitation would be to determine $z_{\text{max}}$ and $z_{\text{min}}$ from Equ. (14) and Equ. (15) for each transformation, and limit the gray values in the domains of each transformation accordingly.

**Experiment 2.**

The experiment is also used to test the performance of the new affine transform. This time we use $256 \times 256 \times 6$ "Lena" as the original image. We also compress the original image using both the traditional method and the method proposed in the paper. But in this experiment, we use two-level partitioning technique which was proposed in[2]. The range block sizes are $8 \times 8$ and $4 \times 4$, and the domain block sizes are $16 \times 16$ and $8 \times 8$. The results are:

When using Jacquin's method, the compression ratio CR=8.5, the PSNR=28.3 dB.
When using the method proposed in the paper, the compression ratio CR=8.4, the PSNR=31.7 dB.

The decoding images are shown in Fig. 6 and Fig. 7.

Experiment 3.

The third experiment is done to verify the contractivity condition theorem Theorem 3.1.1. In the coding of the original image, for any range block, we must search for the most similar domain block and calculate the optimal parameters. As mentioned in Section 4.2, some parameters do not satisfy the contractivity condition. We have to examine the parameters and process them. So in order to test the efficiency of the Theorem 3.1.1, we compress the original image in two different ways. First we examine the parameters and process them to make every parameter satisfy the contractivity condition, the decoding procedure can converge to a good image; Then if we omit the examination and processing procedure, the decoding procedure does not converge, whether use the limitation in Experiment 1 or not, the decoded image is disorderly, it is shown in Fig. 8.
